INDEPENDENT CONSULTANTS:

SWAT MAPS Service Fees

Variable Rate Fertilizer & Seed: Mapping, Zoning, Prescriptions

Mapping/SWAT MAPS Development of New Fields: High grade elevation/EC, zone map development, drainage files (1st year only, one-time fee - payable upon completion)

Soil Sampling & Analysis: Sampling of 5 zones, NPKS, OM, B, Cl, Zn, Cu

| Mapping/ SWAT MAPS Development | | Soil Sampling & Analysis |
|--------------------------------|----------------------------------|--------------------------|
| \$5.00 | complete farm clients > 20,000ac | \$1.50 |
| \$5.50 | complete farm clients | \$2.00 |
| \$6.25 | >1000ac booked at once | \$2.25 |
| \$7.00 | <1000ac booked at once | \$2.50 |

Prescription Files for Controllers: (payable when developed, typically April invoice)
\$1.00/ac (prescriptions for one application such as multi-tank air-cart seeding)
\$50/field (prescription files for additional applications such as floater or fall NH3)

Agronomic Evaluations:

\$0.50/ac for fertility planning & MAPS reports - two trips for plant stand counts and pre-harvest assessment included

Licensed Independent Consultants: You choose the level of service you are willing to provide for your customers.

1st Year: fields custom mapped for SWAT MAPS using one of our licensed service provider packages. Independent consultants can: ground truth, soil sample, write prescriptions, scout fields and support clients.

Subsequent Years: independent consultants retain the client and own the data to do the service; requires ADMS and CropRecords software to conduct the service. Visit CropRecords.com to download software.

Nitrate test compared to Mineralizable N test – NW10

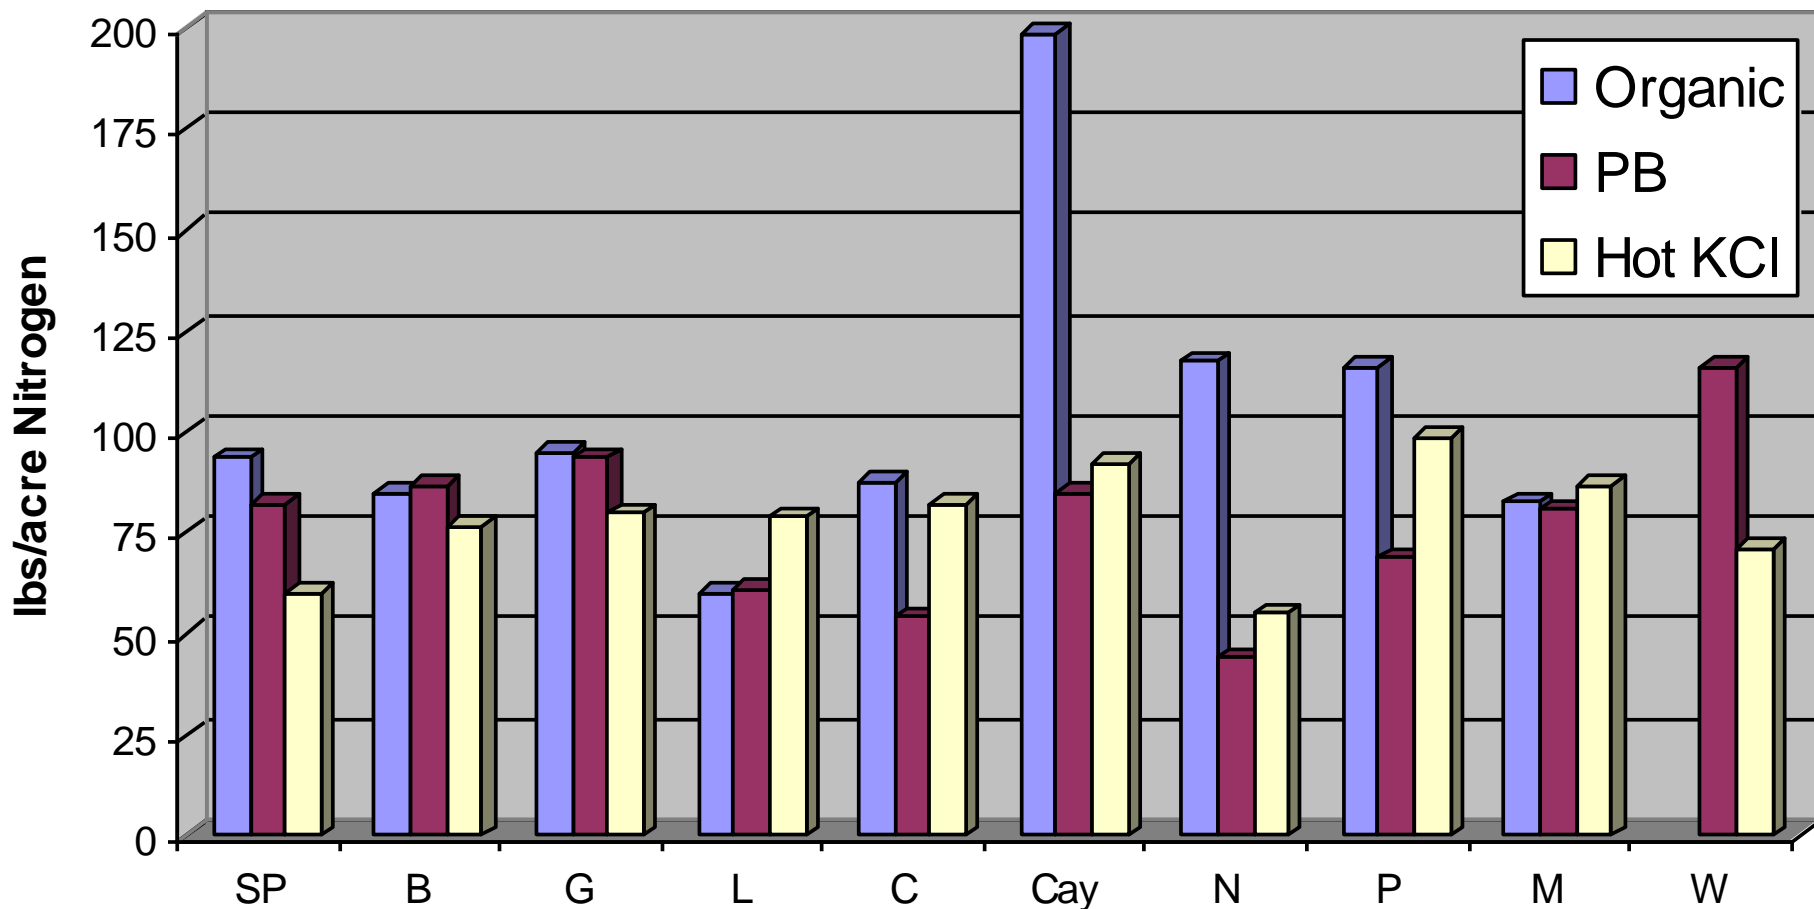

Soil Variability – NW10

NW10 Organic Matter vs. Landscape Position

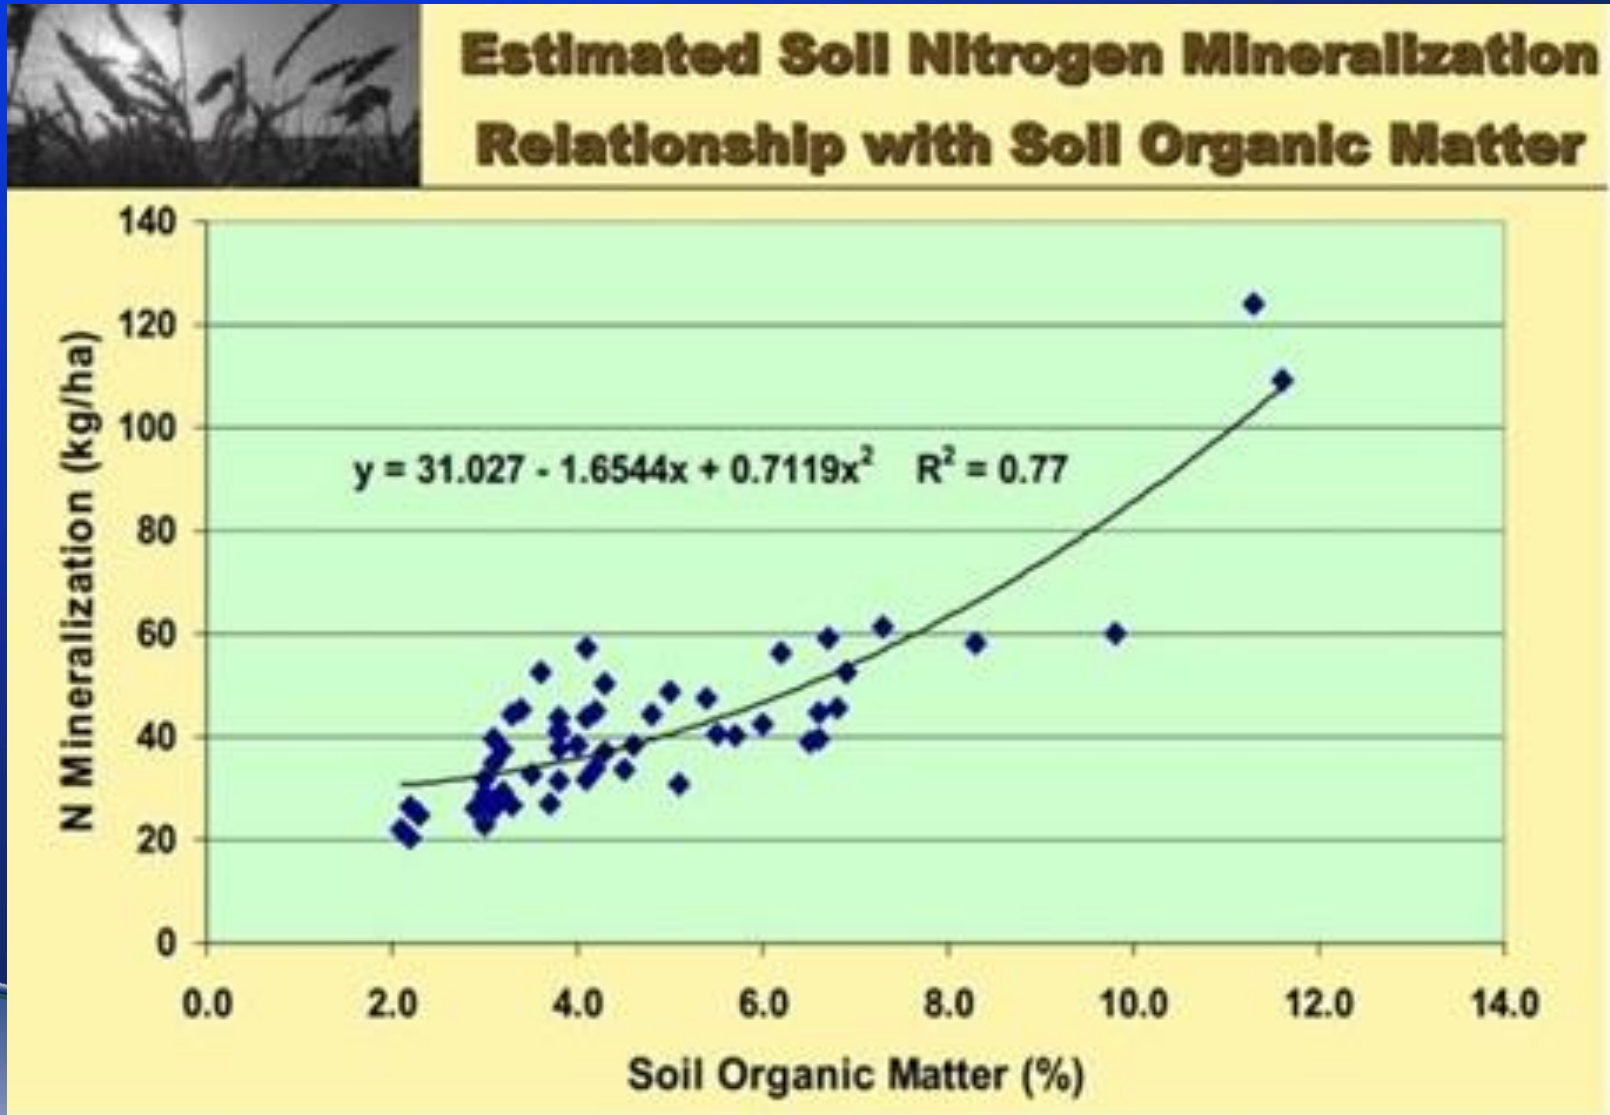

Comparison of Actual Mineralization versus Predicted

Mineralization of N from OM

Ross McKenzie, Alberta Ag

Dr. Dan Pennock (U of S)

Source: 2001 Edmonton SSM Conference Proceedings

- “A very consistent finding in the scientific literature is that variable rate fertilizer prescriptions based on standard soil test procedures have generally been unsuccessful”
- “nitrate-N procedures are a poor indicator of the amount of N that will become available from the soil organic matter over the course of the growing season”

Summary - Mineralization

- The most important component of your nitrogen fertility program to understand
- Rates of mineralization appear to significantly exceed traditional thinking
- Mineralization is at least 5X more important than nitrates, is topography related and more efficiently used
 - Similar N03 tests mean very little if you don't get a decent Nmin estimate

What is the starting point of creating maps for fertility?

Collect data?

Yield?

Imagery?

What is the Starting Point?

Les Henry

- ❑ “Basic information about the soils, topography, agronomic history and area climate should be the starting point”
- ❑ “At the same time as EC is mapped a topographic map can also be made”
- ❑ “It is all about water”

Fertilizer Response Variability

□ Soil

- Topsoil depth and organic matter levels
- salinity, sandy to heavy clay soils, peat soils, solonetzic influence yield potential and fertilizer response

□ Water

- Most profound factor on yields and fertilizer response, where is it dry (knolls) versus wet (depressions)
- Mobile nutrients moving in water

□ Topography

- Landscape position (knoll-midslope-depression) influences moisture, erosion history, organic levels, pH, soil fertility levels

Sulphur levels?

S: 60 lbs/ac

S: 200 lbs/ac

S: 20 lbs/ac

Phosphorus levels?

Phos: 8ppm

pH: 8.0

Phos: 20ppm

pH: 7.8

Phos: 3ppm

pH: 8.2

Wheres the Water?

Water accumulation areas

High OM – more stored water

Water runoff areas, less snow

Low OM – less stored water

The A, B, C's of Soil

A young, rich glacial lacustrine soil near Melfort, SK.

For the majority of prairie soils, time as a soil forming factor is a non-issue. Recent events, such as river floodplains result in alluvium soils that are very, very young with so little soil development that they exhibit no well defined soil profile. Which brings us to the issue of soil profiles.

The A, B, C's of Soil – the Soil Profile

The end result of 10,000 years of soil formation is the soil profile. If we examine a soil from the surface to a depth of a meter or so, we usually see several layers with very different color, structure and chemical composition. The layers are referred to as soil horizons. The horizons from the surface to the unchanged parent material constitute the soil profile.

A Horizon: the A horizon is the topsoil which is the layer of organic matter accumulation. The color will vary from brown to black, depending upon the climate and vegetation which combine to determine the amount of organic matter that can accumulate.

An Ae (e = eluviated = washed out = leached) is a special type of A horizon that is washed out, grey in colour and has platy structure.

B Horizon: the B horizon is usually reddish brown in color and may contain accumulations of constituents washed down from the A horizon. Clay is the major accumulation product in B horizons but iron and sodium are other candidates. The B horizon can often exhibit an easily recognizable columnar or prismatic structure.

C Horizon: the C horizon is the more or less unweathered parent material – stated this way because C horizons can contain a significant accumulation of lime (CaCO_3) that has been washed out of the A and B horizons. Lime accumulation layers are designated Cca. The occurrence of a distinct Cca horizon is a characteristic of semi-arid soils. The depth-of-lime accumulation represents the long-term average depth of entry of water from rain or snow melt.

Practical Note 3.1: The Cca Horizon

The Cca horizon, or lime accumulation layer is an important concept in the understanding of prairie soils. The depth-to-lime provides a 10,000 year record of the volume of water that has passed through a soil. Distinct accumulation layers of lime occur where water rarely passes through the soil and the depth to the Cca is the average depth of penetration of rain water or snow melt.

Portions of a landscape that have a distinct Cca horizon likely contribute little to ground-water recharge. Recharge occurs in sloughs where the lime layer is deep and diffuse.

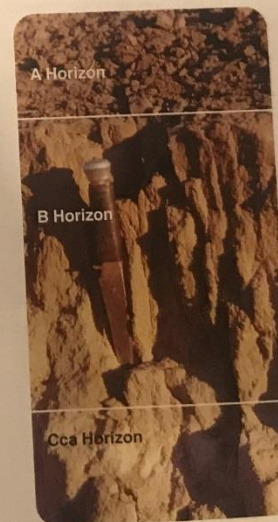

Because it is an accumulation layer there is a school of thought that says the lime accumulation layer should be designated Bca. Another school of thought reserves the B horizon for accumulations of clay, iron, organic matter or sodium. When one examines a Cca, it has characteristics more like a C horizon than a B horizon. Right or wrong, the C horizon advocates won out and we refer to a lime accumulation layer as a Cca.

The average depth of the soil profile is about one meter, but it can vary from 0.5 meters to several meters in depth. Refer back to Figure 3.1 from the Redberry Lake area of Saskatchewan where the soil profile depth (depth-to-lime) in a slough is 3.5 meters.

The best way to learn about soil profiles is to look at them.

Soil Organic Matter and the Soil Zones

In the Canadian Prairies, the end result of 10,000 years of soil formation was broad Soil Zones with similar soil organic matter and soil profiles. The frontispiece map shows the soil zones. Table 3.1 provides information on the organic matter content of the A horizon in the various soil zones.

Table 3.1 Organic Matter and Nitrogen Content of Prairie Soils

| Soil Zone | Native | Cultivated | | |
|-------------|--------|--|------------------|---------------------|
| | | Organic Matter of A Horizon (percentage) | A Depth (inches) | Total N** (lb/acre) |
| Brown | 4 | 2.5 | 3 | 1250 |
| Dark Brown | 6 | 3.5 | 4 | 2333 |
| Black | 8 | 6.5 | 6 | 6500 |
| Thick Black | 10 | 7.5 | 12 | 15000 |
| Grey-Black | 8 | 4.5 | 6 | 4500 |
| Grey | * | 3.5 | 4 | 2333 |

* The organic matter content of the leaf litter of Grey soils is 30 - 40% but upon cultivation most of that is lost, leaving a cultivated A horizon low in organic matter.

** Total N data is for the A depth indicated.

RULE OF THUMB

Soil Organic Matter and Nitrogen

The total N content of a soil multiplied by 20 gives an approximation of the organic matter content of a soil.

$$\% N \times 20 = \% OM$$

or we can say $\% OM / 20 = \% N$.

Remember that the weight of an acre to 6 inches is 2,000,000 pounds.

So, 1% OM will be 20,000 pounds of OM.

$$\text{And } OM/20 = N \\ 20,000/20 = 1000$$

Therefore for each of 1% OM there will be 1000 lb/acre of total N to a depth of 6 inches.

The above data are approximate and are meant as a general guideline only. Considerable variation occurs around the average value. Ranges in values would be a more realistic, but more cumbersome method of expressing the data. Within one soil zone the organic matter content will increase along with the clay content. Thus, clay soils will be higher in organic matter than medium textured soils, which will be higher than sandy soils.

1. Artesian Discharge

In the artesian discharge model, groundwater flow in an aquifer 'pinches out' to a valley, no pressure will build up. Where no such natural pressure from the aquifer provides a constant upward flow, it maintains a high water table even under dry climatic conditions common in saline areas where artesian discharge is the cause.

EC cannot help make VR strategies more consistent

RESULT: Soil electrical conductivity (EC) measurements could improve the accuracy and effectiveness of these zones and the crop response predictions and prescriptions used on these zones.

The study compared two EC sensors: EM38-MK2 (EM38) and Veris MSP3 (Veris). Soil EC maps from both sensors were found to be strong and consistent indicators of the presence of clay and soil moisture. However, the study revealed that mapped EC data could not be used for a direct estimation of the spatial distribution of macronutrients in the soil.

The project then tested five different zone delineation methods in each of the 10 fields studied. They were:

- SURFACE GEOGRAPHY:** Zones were created using a subjective assessment of visual spatial differences in terrain, moisture, salinity, etc.
- GRID SOIL SAMPLING:** Soil sample nitrogen measurements were spatially interpolated using the kriging method. Resulting values were divided equally into three zones.
- HISTORIC YIELD:** All available yield maps were normalized, then pooled to create an average normalized yield map. Resulting values were divided into three zones equally.
- EC:** A single EM38 deep EC map was put through a cluster analysis procedure to objectively determine zone boundaries and number of zones.
- COMPOSITE:** A single representative EM38 deep EC layer and a single representative yield layer were pooled and put through a cluster analysis procedure to objectively determine zone boundaries and number of zones.

conductivity (EC)
measurements
could improve the
accuracy and
effectiveness of
these zones and
the crop response
predictions and
prescriptions used
on these zones.

Satellite images, historical yield maps, terrain analysis and representative soil samples are often used in various combinations to characterize different zones. Farming Smarter initiated this study to see if soil electrical conductivity (EC) measurements could improve the accuracy and effectiveness of these zones and the crop response predictions and prescriptions used on these zones.

The study compared two EC sensors: EM38-MK2 (EM38) and Veris MSP3 (Veris). Soil EC maps from both sensors were found to be strong and consistent indicators of the presence of clay and soil moisture. However, the study revealed that mapped EC data could not be used for a direct estimation of the spatial distribution of macronutrients in the soil.

The project then tested five different zone delineation methods in each of the 10 fields studied. They were:

SURFACE GEOGRAPHY: Zones were created using a subjective assessment of visual spatial differences in terrain, moisture, salinity, etc.

GRID SOIL SAMPLING: Soil sample nitrogen measurements were spatially interpolated using the kriging method. Resulting values were divided equally into three zones.

HISTORIC YIELD: All available yield maps were normalized, then pooled to create an average normalized yield map. Resulting values were divided into three zones equally.

EC: A single EM38 deep EC map was put through a cluster analysis procedure to objectively determine zone boundaries and number of zones.

COMPOSITE: A single representative EM38 deep EC layer and a single representative yield layer were pooled and put through a cluster analysis procedure to objectively determine zone boundaries and number of zones.

All five methods had some level of success at identifying regions that yielded differently from one another. However, the study could not consistently identify an effective variable nitrogen management strategy for these zones.

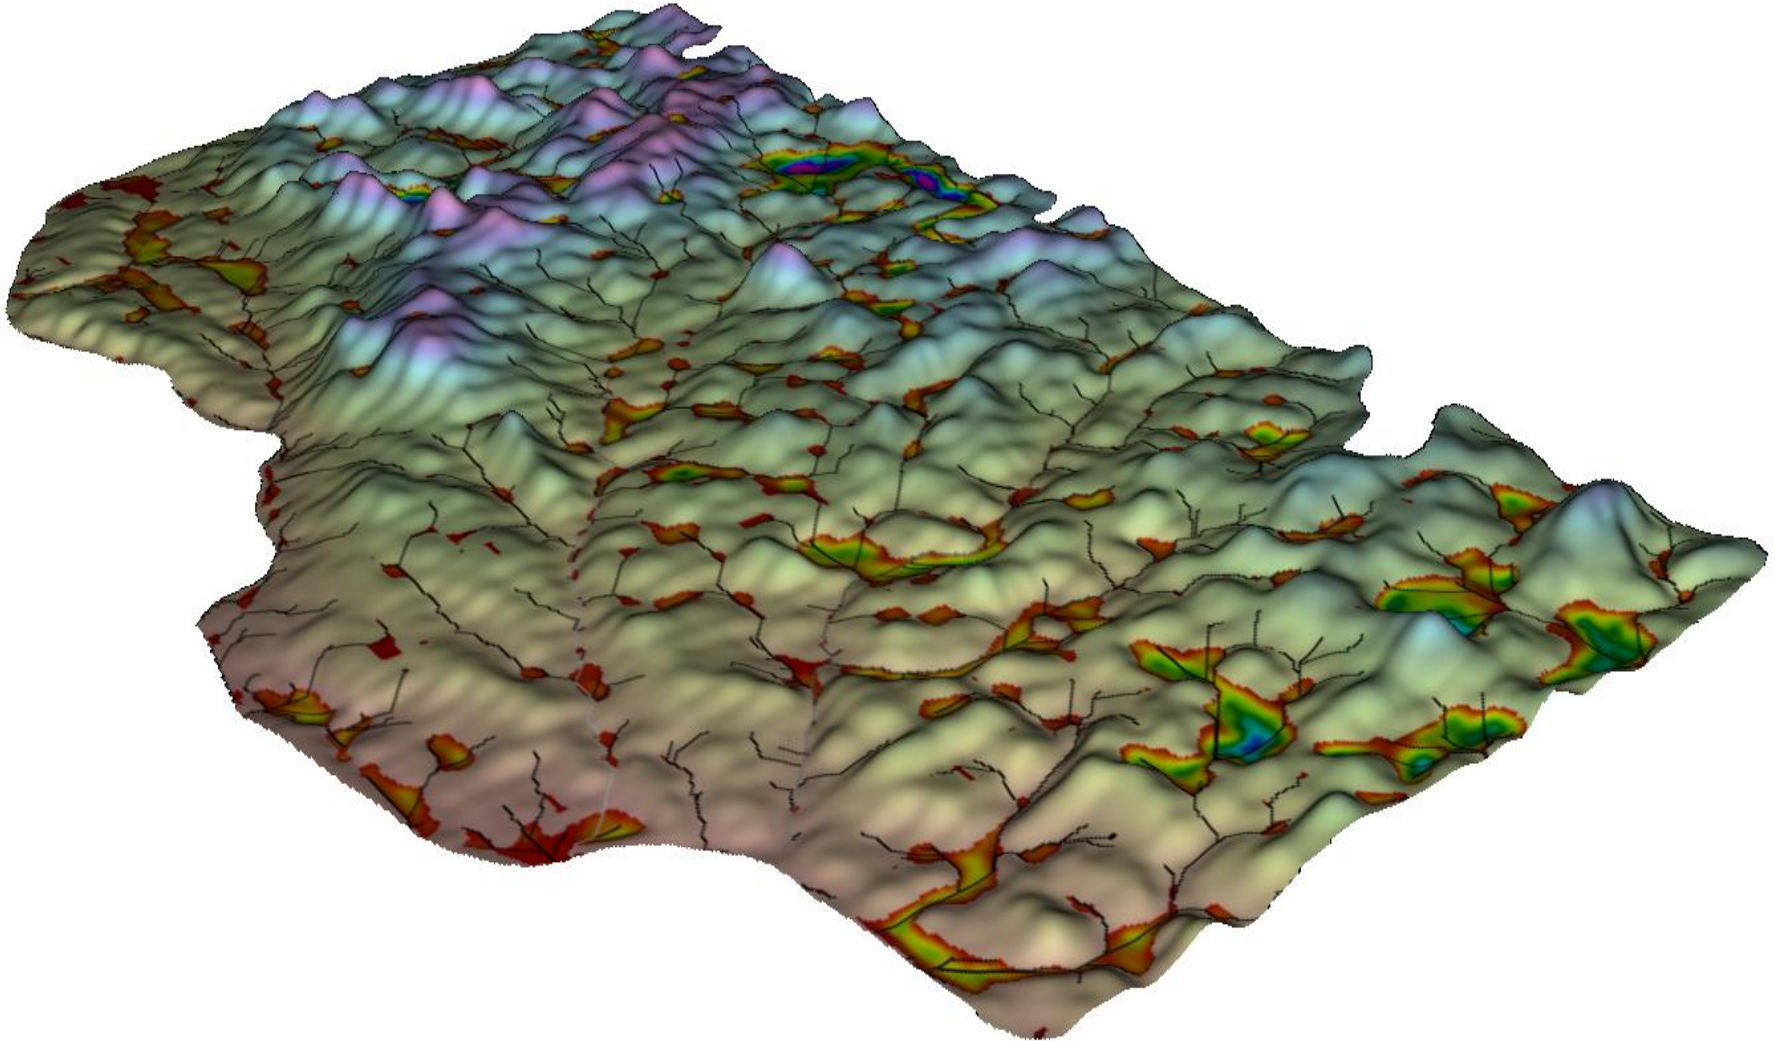

Among the zone delineation methods, there was reasonable success identifying regions that yielded differently from one another, as the study did so in about 50 per cent of instances. These results varied across delineation methods, with the grid soil sampling method being notably less effective than the others. However, the project was unable to consistently identify unique yield responses to nitrogen, indicating that grain yields in the zones identified did not respond differently to nitrogen.

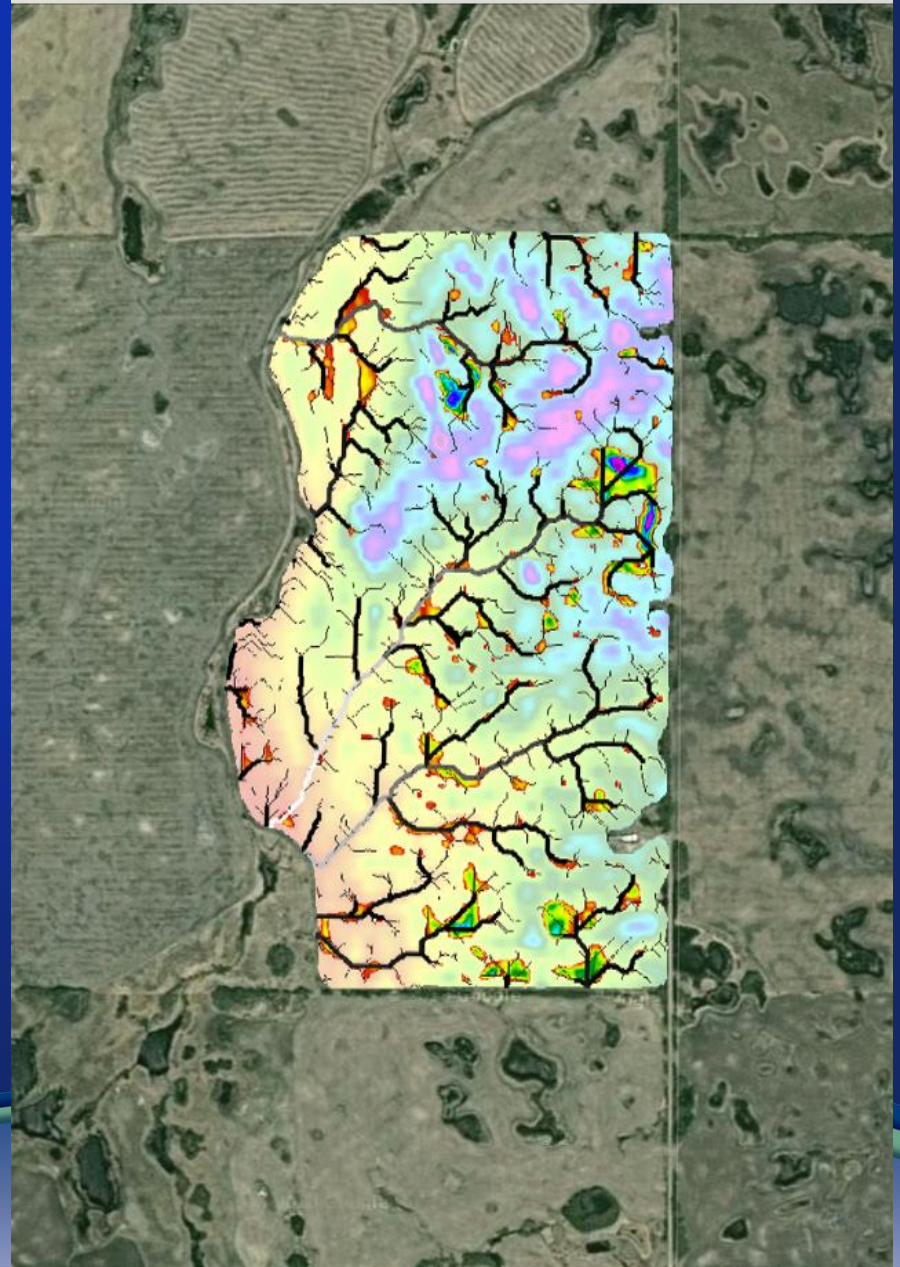

Yield correlated with EC data in roughly 20 per cent of instances, on average, but this fluctuated significantly by year. Correlation exceeded 30 per cent of instances for 2010 and 2013 yield data but was as low as zero per cent for 2012. This shows how variable yield patterns can be from year to year. In fact, yield maps from various years only had strong correlations to one another in 10 per cent of instances project-wide. Elevation correlated strongly with yield data in 26 per cent of instances. This places significant limits on the capability of soil sensor or elevation data to predict grain yield in a given field in a given year.

The study found that universal strategies for zone delineation were largely ineffective, which begs for close scrutiny of VR strategies. It is unlikely that the strategies tested would help a producer reduce nitrogen inputs and associated costs.

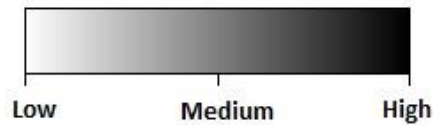

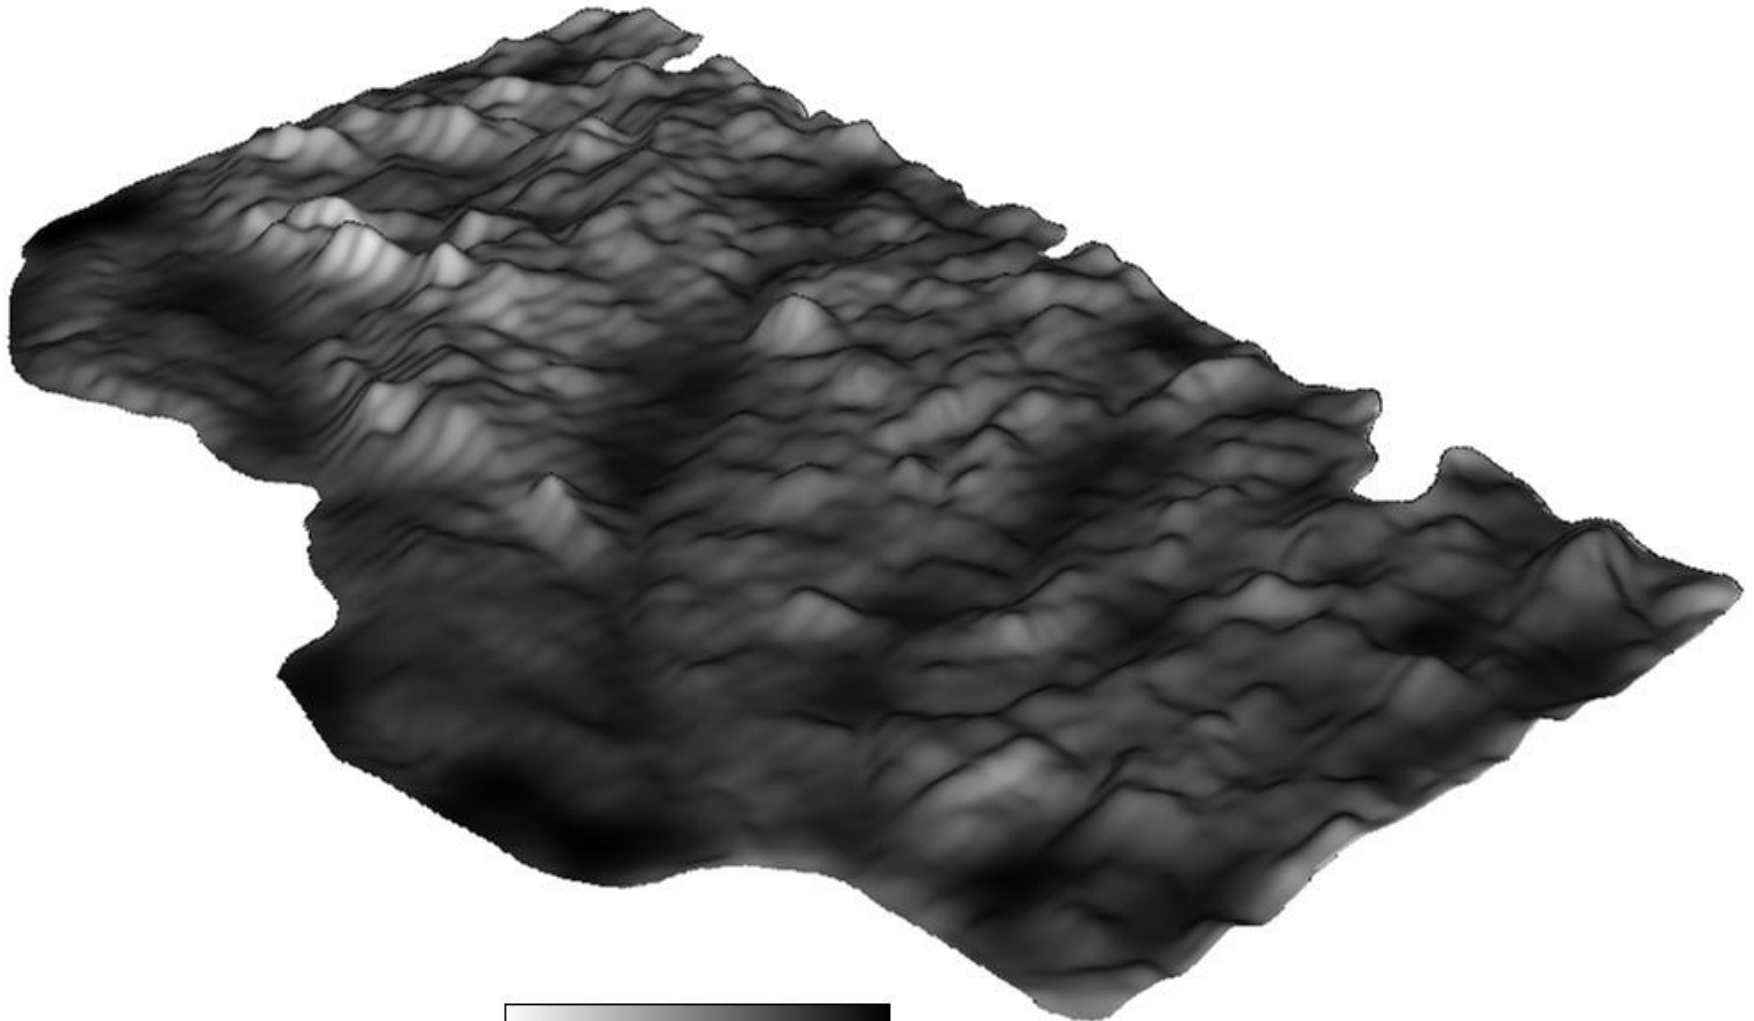

In conclusion, this study questions the viability of a formulaic approach to zone delineation and management. Producers should be prepared to develop a specific variable-rate strategy for each field each year. 🌱

1. Artesian Discharge

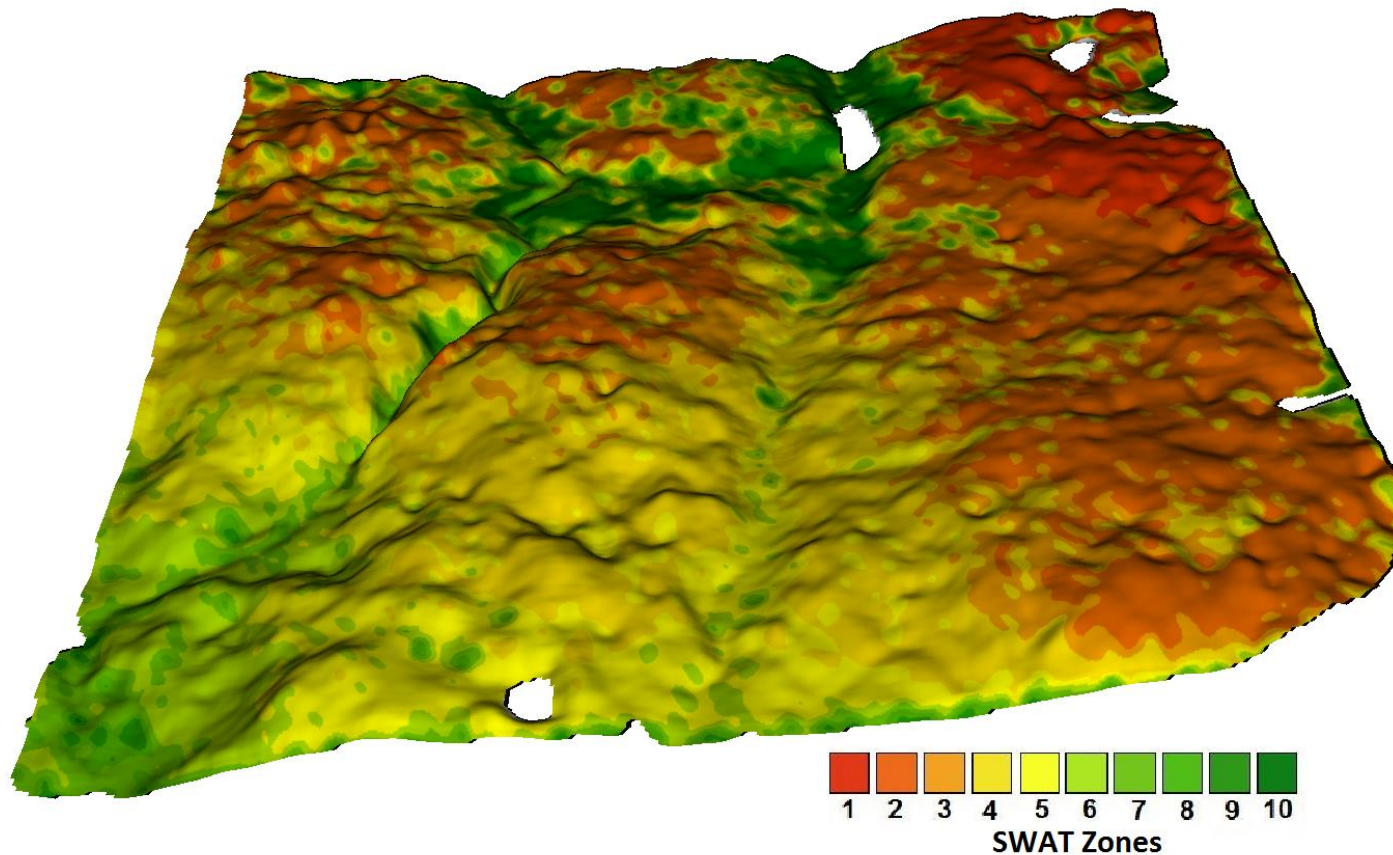

In the artesian discharge model, groundwater flow in an aquifer results in high pressure conditions where the aquifer 'pinches out'. If an aquifer drains as springs to a valley, no pressure will build up. Where no such natural drainage exists, pressure from the aquifer provides a constant upward flow component that maintains a high water table even under dry climatic conditions. Flowing wells are common in saline areas where artesian discharge is the culprit.

D or Deficient, L or Low, S or Sufficient, H or High, E or Excessive

What would you expect the
typical % protein trend
to be in the field?

Trend in %N and Protein

Wheat Protein Trend by Zone (19 fields)

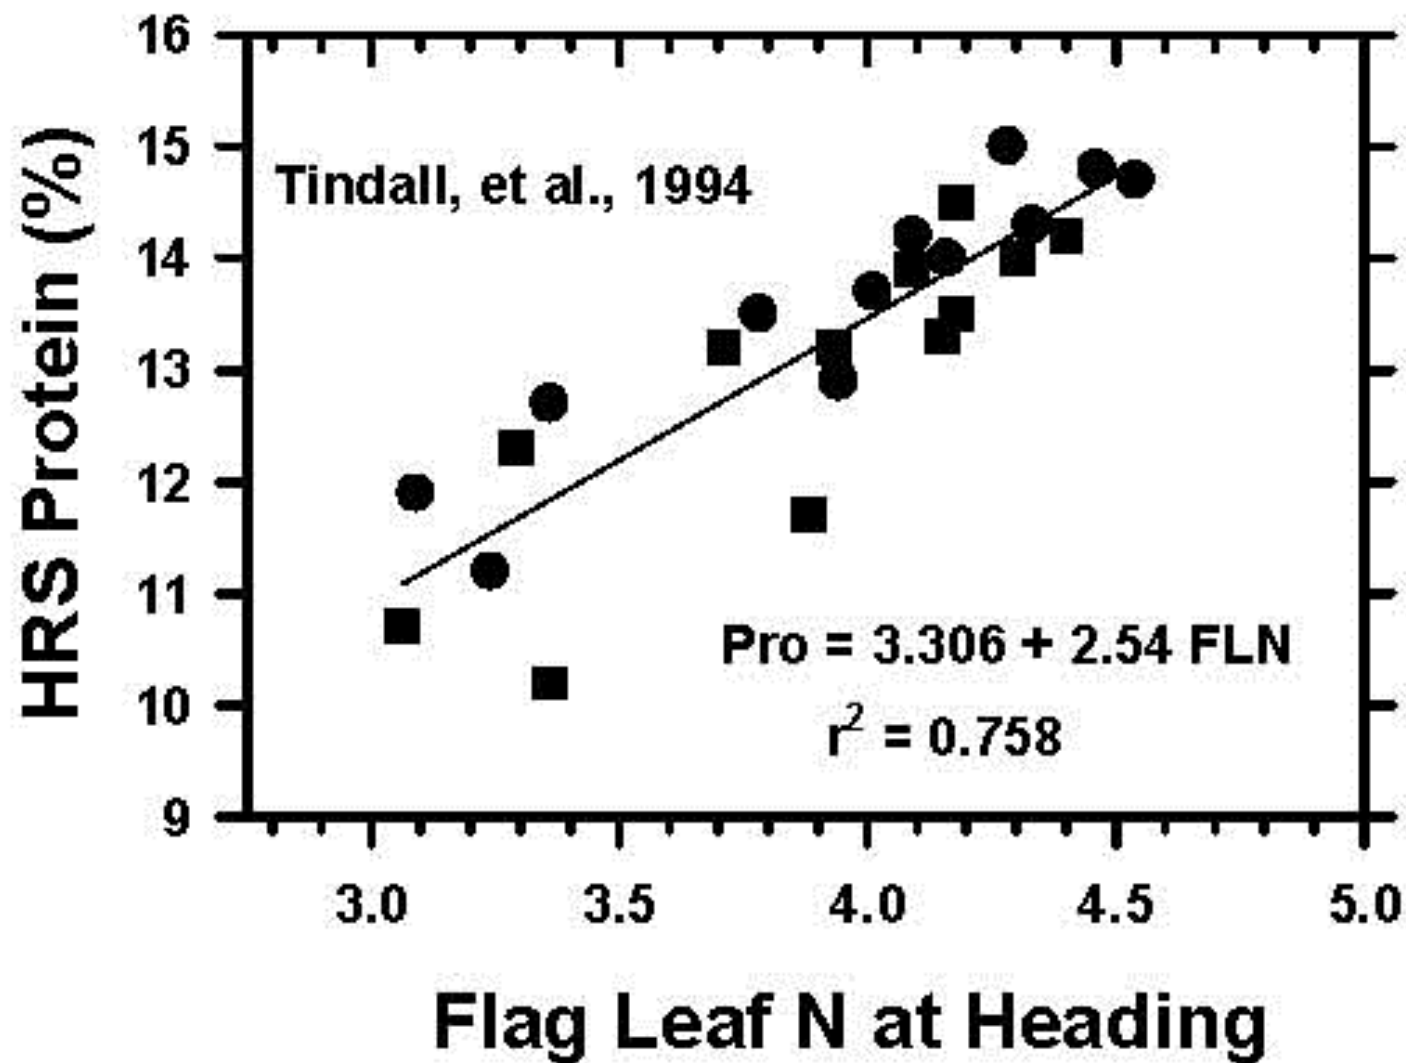

37% (10)

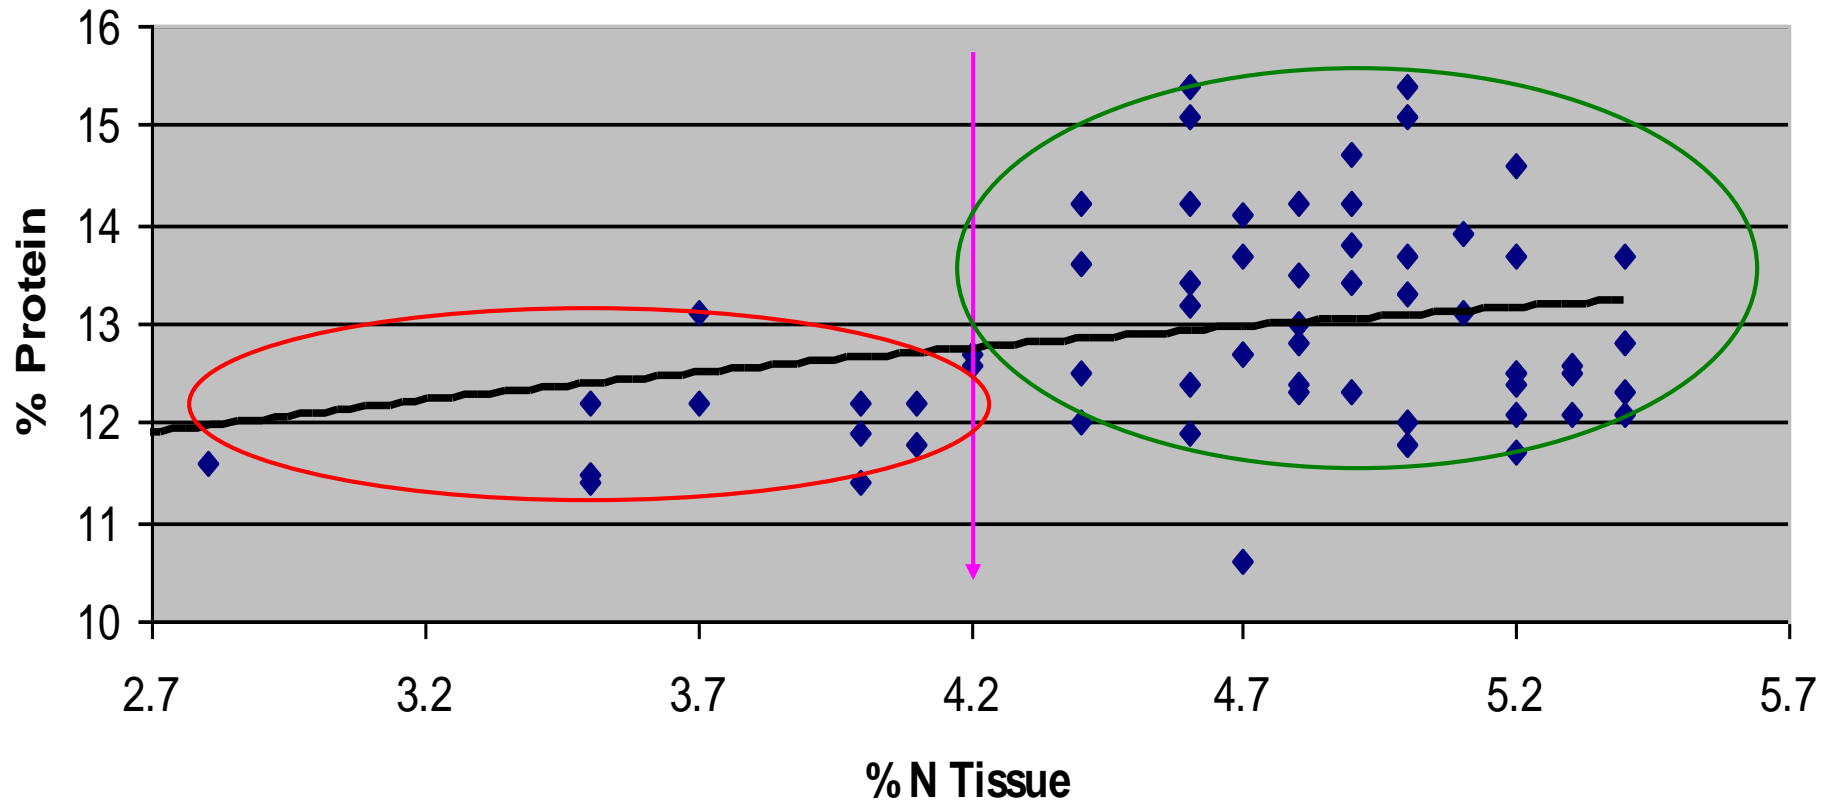

56% (15)

7% (2)

Wheat and Barley Trend?

Wheat Tissue Test versus Protein (64 samples)

Adam Gurr – Agritruth

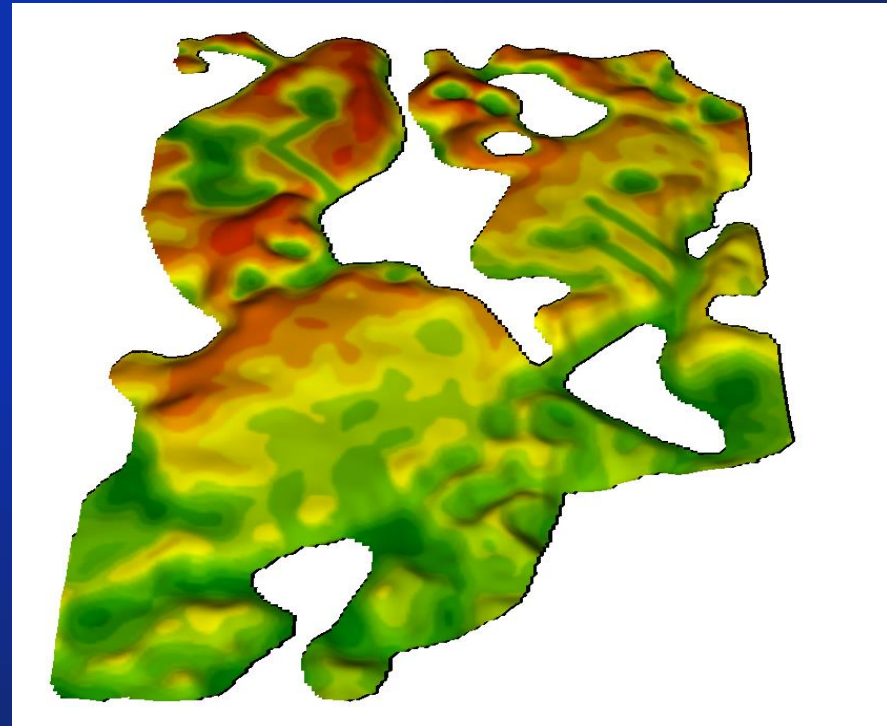

Faller wheat maps

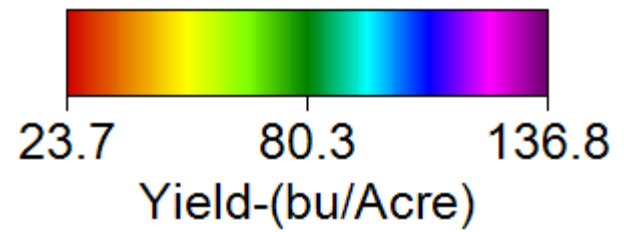

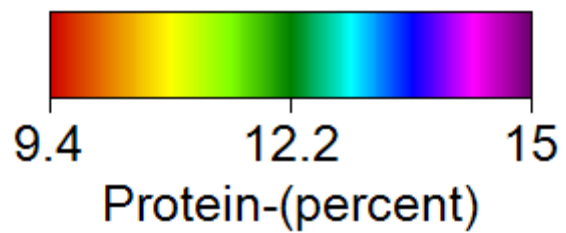

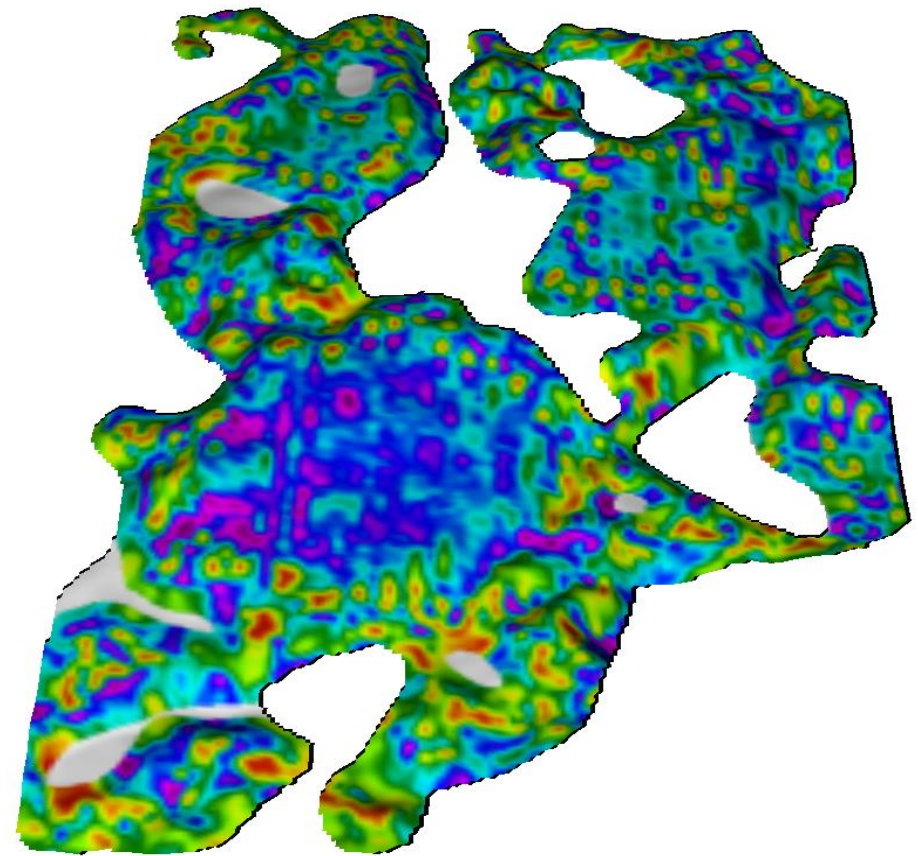

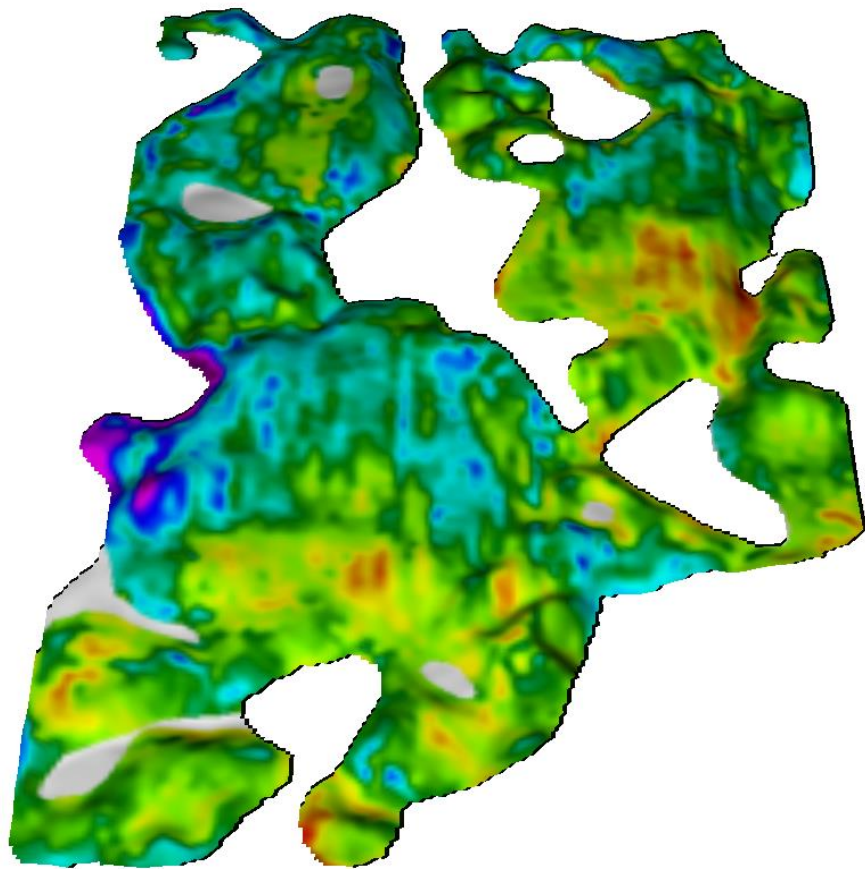

Features

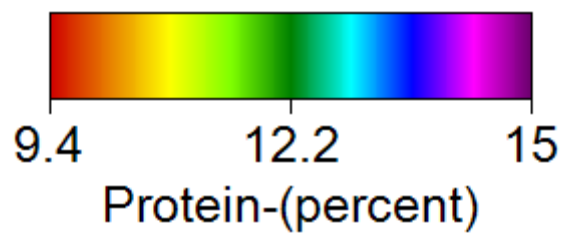

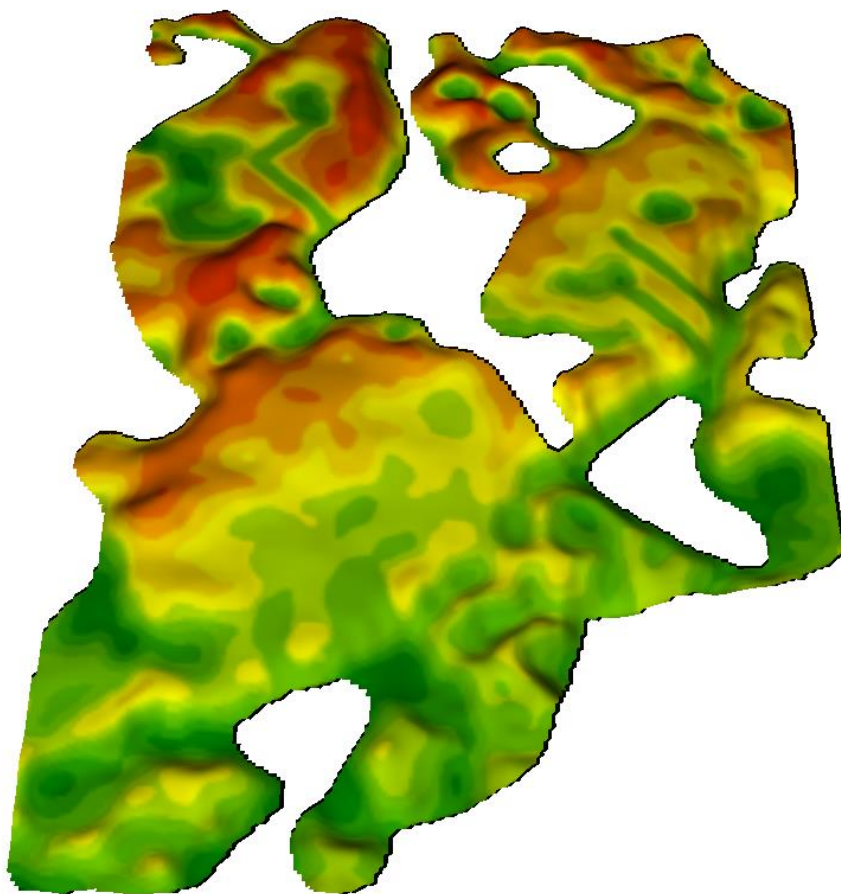

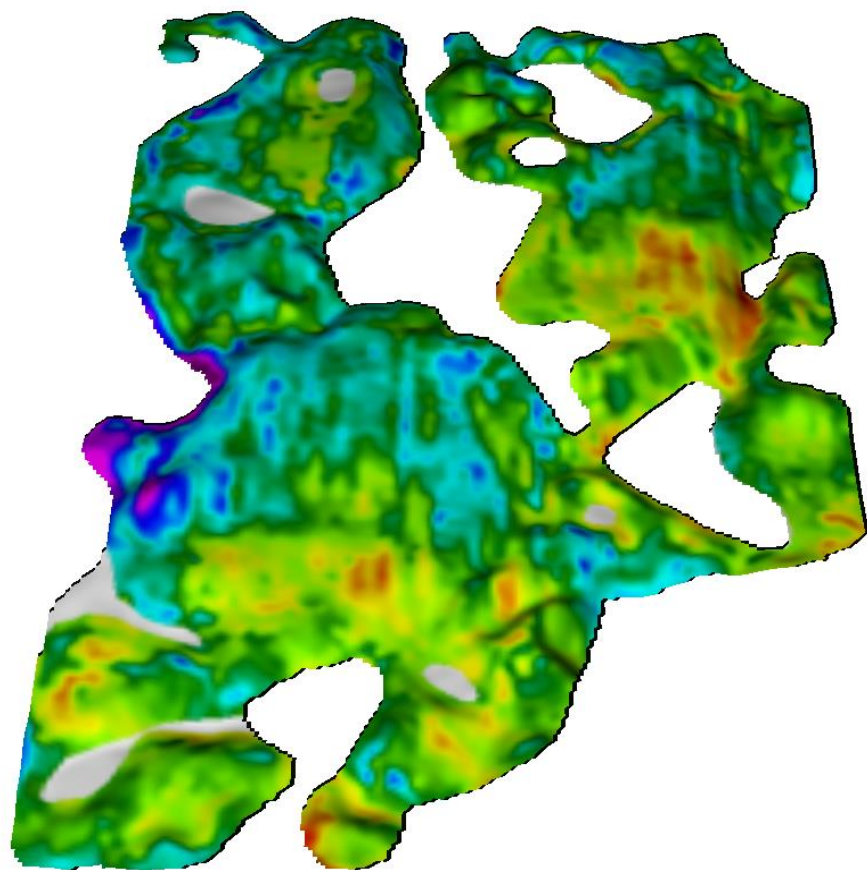

- Real Time Protein, Moisture and Oil results
- Paddock Mapping
- Bin by Bin Averaging
- Data Management Tool
- Cloud Base Data storage
- Sample Scan every 10-15 seconds
 - 3500 measurements per day
 - 150,000 measurements per harvest

Is % Protein mostly influenced
by Yield? Or N min potential?
Or Water?

Protein and % N Summary

- Potential to use %N at flag to predict potential response to N to boost protein
- Over 4.2% odds of a protein boost are low
- In 2012 about 1/3 of fields showed higher protein on zone 1,2 or else trended flat
- Overall trend to high end of %N in all crops in all zones
